Abstract

Observations from the SEAC⁴RS aircraft campaign over the southeast United States in August–September 2013 show NO/NO₂ concentration ratios in the upper troposphere that are approximately half of photochemical equilibrium values computed from Jet Propulsion Laboratory (JPL) kinetic data. One possible explanation is the presence of labile NOₓ reservoir species, presumably organic, decomposing thermally to NO₂ in the instrument. The NO₂ instrument corrects for this artifact from known labile HNO₃ and CH₃O₂NO₂ NOₓ reservoirs. To bridge the gap between measured and simulated NO₂, additional unaccounted labile NOₓ reservoir species would have to be present at a mean concentration of ~40 ppt for the SEAC⁴RS conditions (compared with 197 ppt for NO₂). An alternative explanation is error in the low-temperature rate constant for the NO + O₃ reaction (30% 1-σ uncertainty in JPL at 240 K) and/or in the spectroscopic data for NO₂ photolysis (20% 1-σ uncertainty). Resolving this discrepancy is important for understanding global budgets of tropospheric oxidants and for interpreting satellite observations of tropospheric NO₂ columns.

Plain Language Summary

We identify large discrepancies between observed NO/NO₂ ratios and models representing our best understanding of the chemistry controlling NO and NO₂ in the upper troposphere over the southeast United States during August–September 2013. We suggest that either unrecognized chemistry or errors in modeled cycling between NO, NO₂, and O₃ could explain this discrepancy. Either explanation will have important implications for global tropospheric chemistry and for the interpretation of satellite observations of tropospheric NO₂.

1. Introduction

Nitrogen oxide radicals (NOₓ = NO + NO₂) are emitted by anthropogenic sources (fuel combustion) and natural sources (lightning, soils, and fires). Anthropogenic emissions degrade surface air quality by producing ozone and nitrate particulate matter and also affect ecosystems through nitrogen deposition. On a global scale, NOₓ increases the concentration of tropospheric oxidants (ozone and OH) with complicated implications for climate forcing (Wild et al., 2001). NO₂ in the upper troposphere and the associated cycling between NO and NO₂ are of particular importance for production of tropospheric ozone and OH (Murray et al., 2013; Newsome & Evans, 2017; Ridley et al., 2017). Recent observations from the SEAC⁴RS aircraft campaign over the southeast United States in August–September 2013 show much lower NO/NO₂ ratios in the upper troposphere than expected from models (Travis et al., 2016). Here we suggest possible explanations for this discrepancy and discuss the implications for global tropospheric chemistry and for the interpretation of satellite NO₂ data.
The SEAC4RS observations over the southeast United States show NOx concentrations averaging 0.20 ppb in the upper troposphere above 8 km (0.11 ppb as NO and 0.09 ppb as NO2), as compared to 0.37 ppb in the boundary layer below 2 km (0.06 ppb NO and 0.31 ppb NO2), and much lower concentrations (averaging less than 0.07 ppb) in the middle troposphere between 2 and 8 km (Travis et al., 2016). Such a “C-shaped” profile reflects influences from fuel combustion in the boundary layer and lightning in the upper troposphere (Bertram et al., 2007; Hudman et al., 2007; Huntrieser et al., 2002; Pickering et al., 1998). The mean observed daytime NO/NO2 ratios in SEAC4RS were 0.44 mol mol\(^{-1}\) in the boundary layer and 1.4 mol mol\(^{-1}\) in the upper troposphere, while the corresponding ratios in the GEOS-Chem chemical transport model sampled along the flight tracks were 0.33 mol mol\(^{-1}\) in the boundary layer and 3.3 mol mol\(^{-1}\) in the upper troposphere (Travis et al., 2016). The NO/NO2 ratio in the model increases rapidly with altitude because of the strong temperature dependence of the NO + O3 reaction (Burkholder et al., 2015), but in the observations this increase is much less.

NO2 measurements in the upper troposphere are prone to positive interferences from inlet decomposition of thermally unstable compounds including HNO4, CH3O2NO2, and other organic nitrates (Bradshaw et al., 1999; Browne et al., 2011; Murphy et al., 2004; Nault et al., 2015; Reed et al., 2016). The Berkeley thermal-dissociation laser-induced fluorescence (TD-LIF) instrument used in SEAC4RS (Day et al., 2002; Thornton et al., 2000; Wooldridge et al., 2010) was specifically designed to minimize and correct for these interferences. Inlet residence time is only 0.23 s, and the NO2 measurement is corrected for partial thermal dissociation of HNO4 (0–11%) and CH3O2NO2 (0–21%) with a calibration accuracy of 5% (Nault et al., 2015). HNO4 and CH3O2NO2 are independently measured with calibration accuracies of 15%, and the CH3O2NO2 measurement has an overall uncertainty of 40%, mainly due to uncertainty in the thermal decomposition rate constant (Nault et al., 2015). An independent NO2 measurement made by chemiluminescence (Pollack et al., 2010) during SEAC4RS was biased high compared to the TD-LIF measurement, likely due to interferences from CH3O2NO2 and HNO4 (Travis et al., 2016). The Berkeley TD-LIF NO2 measurements in the upper troposphere have been used in previous work to interpret NOx chemistry (Nault et al., 2016), lightning NOx emissions (Nault et al., 2017), and satellite observations of NO2 columns (Choi et al., 2014; Laughner & Cohen, 2017).

The model-measurement discrepancy in NO/NO2 partitioning in the upper troposphere has consequences not only for tropospheric chemistry but also for interpreting solar backscatter NO2 observations from satellites. It is generally assumed that the tropospheric NO2 column retrieved from satellites is mainly contributed by the boundary layer (Lamsal et al., 2014; Laughner et al., 2016; Martin et al., 2002) and can therefore be related to local NOx emissions (Martin et al., 2003). However, the NO2 vertical profiles from SEAC4RS imply a 35–50% contribution of the upper troposphere to the NO2 tropospheric column observed from satellite (Travis et al., 2016), because sensitivity of backscattered solar radiation to NO2 increases by a factor of 3 from the surface to the upper troposphere (Martin et al., 2002). Better understanding of this upper tropospheric NO2 is crucial to the use of satellite data for estimating surface NOx emissions.

Previous work starting in the 1990s has found varied levels of agreement between NO/NO2 ratios observed from aircraft and model photochemical equilibrium computed from local conditions. Early work in the lower stratosphere found models to be too high by 20–30% (Cohen et al., 2000; Del Negro et al., 1999; Jaeglé et al., 1994; Sen et al., 1998). Observed NO/NO2 ratios in the upper troposphere during the PEM-West A campaign over the tropical Pacific were three times lower than model predictions, which was attributed to NO2 measurement interferences (Crawford et al., 1996), although Davis et al. (1996) also hypothesized a role of halogen chemistry. Bradshaw et al. (1999) found model agreement with observations to within 30% in the upper troposphere over the tropical Pacific using an improved NO2 instrument that avoided positive interferences through short inlet residence time. More recent model studies of the upper troposphere have again found an overestimate of observed NO/NO2 ratios (Travis et al., 2016; Williams et al., 2017) and attributed it to underestimate of peroxy radicals converting NO to NO2.

2. NO-NO2 Cycling in the Upper Troposphere During SEAC4RS

According to current understanding, the NO/NO2 ratio in the daytime upper troposphere is determined by rapid chemical cycling through the reactions in Table 1. Here we calculated the mean rates of individual

aMain reactions cycling NO and NO₂ in the daytime upper troposphere (8–12 km) over the southeast United States. Mean rates are calculated using JPL kinetic data (Burkholder et al., 2015) applied to SEAC4RS aircraft observations (NO, NO₂, O₃, JNO₂, temperature, and pressure) over the southeast United States (94.5–76.7°W, 30–37°N) in August–September 2013 and with radical concentrations (NO₂, halogens) computed by the GEOS-Chem model along the flight tracks (Travis et al., 2016, 2017; Sherwen et al., 2016). Only reactions with rates above 1 × 10^6 molecules · cm⁻³ · s⁻¹ are listed. Data outside the 9–15 solar time window and in stratospheric air ([O₃]/[CO] > 1.25 mol mol⁻¹) have been excluded. Error standard deviations are calculated by propagation of measurement, rate constant, and GEOS-Chem radical concentration errors (precision).bPrecision of the O3 measurement (3%; Ryerson et al., 2000).cPrecision of the NO measurement (4%; Ryerson et al., 1998).dPrecision of the kinetic rate constants (30% for NO + O₃, 15% for NO + HO₂, NO + CH₃O₂, NO + BrO, and NO + ClO, and 20% for NO + IO; Burkholder et al., 2015).eUncertainty in the GEOS-Chem HO₂ concentration (30%) estimated from the H₂O₂ measurements in SEAC4RS (Crouse et al., 2006). The same relative error is assumed for CH₃O₂. fUncertainty in the GEOS-Chem BrO, IO, and ClO concentrations (50%; Sherwen et al., 2016).gPrecision of the NO₂ measurement (5%; Nault et al., 2015), the measured UV-A actinic flux (5%; Shetter et al., 2003), and the NO₂ cross section and quantum yield (20%; Sander et al., 2011).

The calculated rates in Table 1 indicate that conversion of NO to NO₂ in the upper troposphere is mainly by reaction with ozone (75%). Reactions with peroxide radicals contribute 18%, and reactions with halogen radicals (BrO, IO, and ClO) contribute 7%. The calculated rate of conversion of NO to NO₂ has an aggregated uncertainty of 32% and balances only half of the NO₂ photolysis rate, which has an uncertainty of 21%. This represents a significant discrepancy, such that a model using JPL kinetics would overestimate the NO/NO2 ratio observed in SEAC4RS.

Figure 1 shows the median observed vertical profiles of the principal variables relevant to NO/NO₂ cycling, along with the corresponding values simulated by the standard GEOS-Chem model along the aircraft flight tracks as in Travis et al. (2016). The NO/NO₂ ratio in the model is over twice that measured in the upper troposphere above 8 km. The bias is systematic over the frequency distribution of the observations (Figure 2) and also extends to stratospherically influenced air ([O₃]/[CO] > 1.25 mol mol⁻¹), although SEAC4RS did not sample the actual stratosphere (maximum ozone concentration was 125 ppb). Travis et al. (2016) attributed the model bias in the NO/NO₂ ratio to an underestimate of peroxide radicals, but that underestimate would have to be a factor of 5 in order to close the budget of Table 1. This is incompatible with the SEAC4RS observations for H₂O₂, which is produced by self-reaction of HO₂ and is thus a sensitive proxy of HO₂ concentrations. Observed H₂O₂ concentrations are 30% higher than GEOS-Chem (Figure 1) but would be grossly overestimated if HO₂ concentrations were increased by a factor of 5. Similarly, simulated BrO concentrations would have to be underestimated by a factor of 20 in order to correct the model bias in the NO/NO₂ ratio. This would be grossly inconsistent with observations (Schmidt et al., 2016; Shah et al., 2016; Sherwen et al., 2016).

We see from Figure 1 that there is no systematic model bias in ozone, temperature, or JNO₂ that would explain an error in the NO/NO₂ ratio. The JNO₂ observations during SEAC4RS are from spectrally resolved actinic flux measurements (Shetter et al., 2003), converted to photolysis frequencies using the same temperature-dependent JPL spectroscopic data (absorption cross sections and quantum yields) as in GEOS-Chem. These spectroscopic data are tabulated by JPL as a function of wavelength at 220 and 294 K and are interpolated linearly for intermediate temperatures. About 90% of JNO₂ photolysis is contributed by wavelengths shorter than 398 nm for which the quantum yield is unity. The estimated JPL uncertainty on JNO₂ is 20% with no temperature dependence (Sander et al., 2011), though laboratory studies show better agreement at surface temperatures (Orphal, 2003; Shetter et al., 2003). Observed photolysis frequencies of other relevant species (O₃, HCHO, H₂O₂, HNO₃, PAN, and CH₃OOH) also agree with GEOS-Chem values to within 1–15% throughout the troposphere.

One possible explanation for the apparent departure of the NO/NO₂ ratio from photochemical equilibrium would be a positive bias in the NO₂ measurement. This could occur if there was an unrecognized labile reservoir of NO₂ (other than HNO₄ or CH₃O₂NO₂) decomposing in the instrument inlet, or if the correction for HNO₄ or CH₃O₂NO₂ was inadequate. We find that that this missing reservoir (likely organic) would need to
be present at a mean concentration of at least 40 ppt in the upper troposphere in order to fit the model NO/NO₂ ratios, assuming 100% decomposition to NO₂ inside the instrument. For comparison, the correction to the NO₂ measurement from the decomposition of CH₃O₂NO₂ was 0–23 ppt (0–21% of NO₂ at temperatures less than 240 K) and 0–20 ppt HONO (0–11%) during SEAC4RS (Nault et al., 2015). The high-flow pump to minimize the influence from these reservoirs malfunctioned in the first five SEAC4RS flights (6–16 August), but these flights were either not over the southeast United States or not in the upper troposphere and are not included in our analysis.

A significant uncertainty in the CH₃O₂NO₂ correction is the thermal decomposition rate constant, which has a JPL 1-sigma uncertainty of 30%. Considering a cabin air temperature of 300 K, an external pressure of 230 hPa, and an inlet residence time of 0.23 s, a 30% increase in the CH₃O₂NO₂ thermal decomposition rate would double the corresponding correction to the NO₂ measurement from 0–23 to 0–46 ppt. The effect would be at most 23 ppt at the upper end of the range and is not sufficient to correct the NO/NO₂ ratio. GEOS-Chem underestimates CH₃O₂NO₂ in the upper troposphere (18 ± 19 ppt modeled, 124 ± 98 ppt observed), reflecting in part the model underestimate of NO₂ but also suggesting missing organic chemistry. A faster thermal decomposition rate for CH₃O₂NO₂ would exacerbate the model underestimate.

Figure 1. Median vertical tropospheric profiles of the NO/NO₂ concentration ratio and related quantities on SEAC4RS flights (9–15 solar time) during August–September 2013 over the southeast United States (94.5–76°W, 30–37°N). Data from urban plumes ([NO₂] > 4 ppb), open fire plumes ([CH₃CN] > 200 ppt), and stratospheric air ([O₃]/[CO] > 1.25 mol mol⁻¹/C₀) are excluded. Observations are compared to GEOS-Chem model results sampled along the flight tracks, for the standard model (Travis et al., 2016), and a sensitivity simulation with reduced JNO₂ and increased low-temperature NO + O₃ rate constant (see bottom right panel). Observed NO₂ is from the Berkeley TD-LIF measurement (Nault et al., 2015). The bottom right panel shows the k₁ (NO + O₃) rate constant versus temperature from JPL in red with 2-sigma uncertainty in gray shading (Burkholder et al., 2015), and sensitivity simulation values resulting in 1.4k₁ (purple) in the upper troposphere. The JNO₂ observations apply JPL spectroscopic data to actinic fluxes measured aboard the aircraft and would be reduced similarly to the model if the spectroscopic data are corrected downward (black dashed line). The dashed purple line in the top left panel shows the NO-NO₂-O₃ photochemical equilibrium values JNO₂(hν)/k₁(T)[O₃] calculated from observed actinic fluxes (hν), temperature (T), and [O₃] with 1.4k₁ and the 20% reduction in JNO₂ applied.
Previous work has postulated missing organic chemistry in the upper troposphere to explain observations of volatile organic compounds (VOCs) including methanol (Jacob et al., 2005), acetaldehyde (Millet et al., 2010), and glyoxal (Volkamer et al., 2015). Aumont et al. (2005) and Mouchel-Vallon et al. (2013) showed how explicit VOC mechanisms produce a cascade of oxidation products globally that are not tracked in models. Bradshaw et al. (1999) did not need to invoke an unknown NOx reservoir to reconcile their model with observations over the tropical Pacific, but the southeast United States may be a more propitious environment for VOC oxidation products to be lifted to the upper troposphere by deep convection (Li et al., 2005).

An alternative explanation for the apparent NO/NO2 departure from photochemical equilibrium would be error in the kinetic data used to compute that equilibrium. Figure 3 shows the International Union of Pure and Applied Chemistry (IUPAC) and JPL recommendations for the temperature dependence of the NO + O3 rate constant k1, along with the individual laboratory data that went into these recommendations. IUPAC recommends $k_1 = 2.07 \times 10^{-12} \text{cm}^3 \cdot \text{molecule}^{-1} \cdot \text{s}^{-1}$ with a 1-σ uncertainty of ±200 K for E/R and a 1-σ uncertainty of 8% for $k_1$ at 298 K (Atkinson et al., 2004). JPL recommends $k_1 = 3.00 \times 10^{-12} \text{cm}^3 \cdot \text{molecule}^{-1} \cdot \text{s}^{-1}$, again with 1-σ uncertainty of ±200 K for E/R and a 1-σ uncertainty of 10% for $k_1$ at 298 K. The IUPAC and JPL rate expression agree to within 4% over the 220–300 K temperature range. For a typical upper tropospheric temperature of 220–240 K the implied 1-σ uncertainty for the JPL rate is 30–40%. However, several studies have suggested a departure from Arrhenius behavior at low temperatures (Figure 3; Birks et al., 1976; Borders & Birks, 1982; Cohen et al., 2000; Michael et al., 1981).

The purple curves in Figures 1 and 2 show the effects in the GEOS-Chem simulation of decreasing $J_{NO2}$ by 20%, and decreasing the activation energy for $k_1$ by 400 K (2σ) relative to the JPL recommendation so that $k_1$ increases by a factor 1.4 on average in the upper troposphere, while remaining at the JPL recommended value at 298 K through adjustment of the preexponential factor. The resulting NO/NO2 ratio in the upper troposphere decreases by 40% from the standard simulation, and Figure 2 shows that the variance in the modeled NO/NO2 ratio decreases by half, becoming more consistent with the observations. One could match the observations if there was in addition a 15 ppt positive bias in the NO2 measurement due to an unaccounted labile NO2 reservoir.

We examined whether the variability of the observed NO/NO2 ratio in the SEAC4RS data set could test the above corrections. For this purpose we used 10-min observations of the ratio along the flight tracks at 8–12 km altitude and correlated them to the local values of the photo-equilibrium constant $J_{NO2}(h)/k_1(T)[O_3]$ for NO-NO2-O3 cycling where the UV actinic fluxes ($h$), temperatures ($T$), and [O3] are taken from the observations. Results are shown in Figure 4. When using JPL values for $J_{NO2}(h)$ and $k_1(T)$, we find a significant ($p < 0.01$) correlation coefficient $r = 0.37$ and a reduced-major-axis regression slope $S = 4.0$. The relatively low correlation coefficient can be attributed to noise and high-frequency variability in the observations. Reducing $J_{NO2}$ by 20% and increasing the low-temperature $k_1$ as described above improves the slope ($S = 2.3$) while not affecting the correlation coefficient.

![Picture of Figure 2](image1)

Figure 2. Probability density function of the NO/NO2 concentration ratio under midday conditions (9–15 local time) in the upper troposphere (8–12 km) during SEAC4RS in August–September 2013. Observations are compared to the standard GEOS-Chem model and the model with $J_{NO2}$ reduced by 20% and the activation energy for the NO + O3 reaction increased so that $k_1$ increases on average by 1.4 in the upper troposphere (purple). The same data criteria as stated for Table 1 are applied.

![Picture of Figure 3](image2)

Figure 3. Temperature dependence of the NO + O3 rate constant $k_1$. The y axis is a log scale, and the x axis is an inverse scale (1/T), so that an Arrhenius dependence plots as a straight line. Recommended rates from JPL (black; Burkholder et al., 2015) and IUPAC (light gray; Atkinson et al., 2004) are shown as solid lines with the 2-σ uncertainty in shading. Laboratory measurements used in the JPL and IUPAC recommendations are shown in circles with their respective uncertainties. The sensitivity simulation resulting in 1.4$k_1$ in the upper troposphere (230–250 K) is shown as the purple line.
Figure 4. Correlation of the observed NO/NO2 concentration ratio with the local photochemical equilibrium constant \( J_{NO2}(hv)/k_1(T)/[O_3] \) under midday conditions (9–15 local time) in the upper troposphere (8–12 km) during SEAC4RS in August–September 2013. Data are 10-min averages along the aircraft flight tracks. The photochemical equilibrium constant is calculated from local aircraft measurements of actinic fluxes \( (hv) \), temperature \( (T) \), and ozone concentrations. Calculations using the JPL recommendations for \( J_{NO2}(hv) \) and \( k_1(T) \) (in red) are compared to calculations reducing \( J_{NO2} \) by 20% and increasing \( k_1 \) on average by 1.4 in the upper troposphere (purple). The solid lines show reduced major axis regressions and the 1:1 line is dashed. Correlation coefficients \( r \) and regression slopes \( S \) are given inset. \( J_{NO2} = 20\% \), 1.4 \( k_1 \), \( r = 0.38 \), \( S = 2.3 \).

\( r = 0.38 \). Excluding the 15% of the data with \([O_3] < 40 \text{ ppb}\) increases the correlation coefficient to \( r = 0.48–0.49 \). Those conditions were associated with particularly high \( J_{NO2} \) (reflecting clouds below) and enhancements in CO and HCHO indicative of recent convective influence (Barth et al., 2015; Fried et al., 2016; Snow et al., 2007).

3. Implications

The apparent departure of the NO/NO2 concentration ratio from photochemical equilibrium in upper tropospheric observations cannot be explained by missing radicals converting NO to NO2, as proposed in previous work, because the required radical concentrations would be far in excess of observational constraints. It must be due either to an unaccounted labile NOx reservoir acting as positive interference on the NO2 measurement or to significant errors in the kinetic data for NO-NO2-O3 photochemical cycling at low temperatures. Either of these possibilities have important implications for upper tropospheric chemistry.

The NO2 measurement specifically excludes interferences from HNO4 and CH3O2NO2, but other labile NOx reservoirs could potentially be measured as NO2 following thermal decomposition in the instrument. The presence of such a reservoir at a concentration of 40 ppt, as needed to explain the observed NO/NO2 ratios, would increase the effective lifetime of NOx by 20% under the SEAC4RS conditions. More importantly, it would likely imply organic chemistry missing from the models, as also suggested by observations of acetaldehyde and glyoxal in the upper troposphere (Millet et al., 2010; Volkamer et al., 2015) and by the large model underestimate of CH3O2NO2 in SEAC4RS.

The rate constants \( J_{NO2} \) and \( k_1 \) involved in NO-NO2-O3 photochemical cycling have relatively small uncertainties in kinetic assessments, and even then are found to be major sources of uncertainty in model simulations of tropospheric oxidants (Bergin et al., 1999; Newsome & Evans, 2017; Ridley et al., 2017; Vuilleumier et al., 1997). When the low-temperature NO + O3 reaction rate constant (1.4 \( k_1 \) and NO2 photolysis frequency \( J_{NO2} = 20\% \)) are adjusted in GEOS-Chem within these uncertainties to improve the simulation of the NO/NO2 ratio in the SEAC4RS upper tropospheric data, we find that simulated ozone decreases by 7 ppb at 8–12 km altitude. This degrades the previously successful simulation of upper tropospheric ozone in the standard model (Travis et al., 2016); however, that simulation overestimated the NO concentration (Figure 1).

Improved understanding of the contribution of the upper troposphere to the tropospheric NO2 column also has implications for retrieving and interpreting NO2 observations from satellites. Spectral fitting of the satellite data in and around the NO2 absorption bands measures the slant column of NO2 along the light path. Conversion of this slant column to the actual vertical tropospheric column requires removal of the stratospheric contribution, followed by division by an air mass factor (AMF) dependent on the vertical distribution of tropospheric NO2 (Martin et al., 2002). The National Aeronautics and Space Administration (NASA) operational retrieval for the OMI satellite instrument (Krotkov et al., 2017) assumes NO2 vertical profiles from the GMI model (Lamsal et al., 2014) that greatly underestimate NO2 concentrations in the upper troposphere as observed by SEAC4RS. The mean AMF over the southeast United States in August–September 2013 is 1.28 using vertical distributions from the NASA operational retrieval but 1.67 when using the median observed profile in Figure 1. This implies that the OMI operational retrieval for NO2 may be 30% too high.

Laughner and Cohen (2017) show that inclusion of lightning NOx in the upper troposphere to match DC3 observations of NO2 increases the OMI AMF by 34% for summertime, further demonstrating the importance of accurately modeling and measuring NOx in the upper troposphere for the interpretation of satellite NO2 measurements.
In conclusion, models significantly overestimate recent observations of the NO/NO2 ratio in the upper troposphere. This cannot be easily explained by known labile NOx reservoirs (HNO3 and CH3O2NO2) interfering with the NO2 measurement. It implies either error in current recommendations for NO-NO2-O3 cycling kinetics or the presence of a missing labile NO2 reservoir, likely organic. Either explanation would have important implications for our understanding of tropospheric oxidants and/or the interpretation of satellite NOx measurements.
